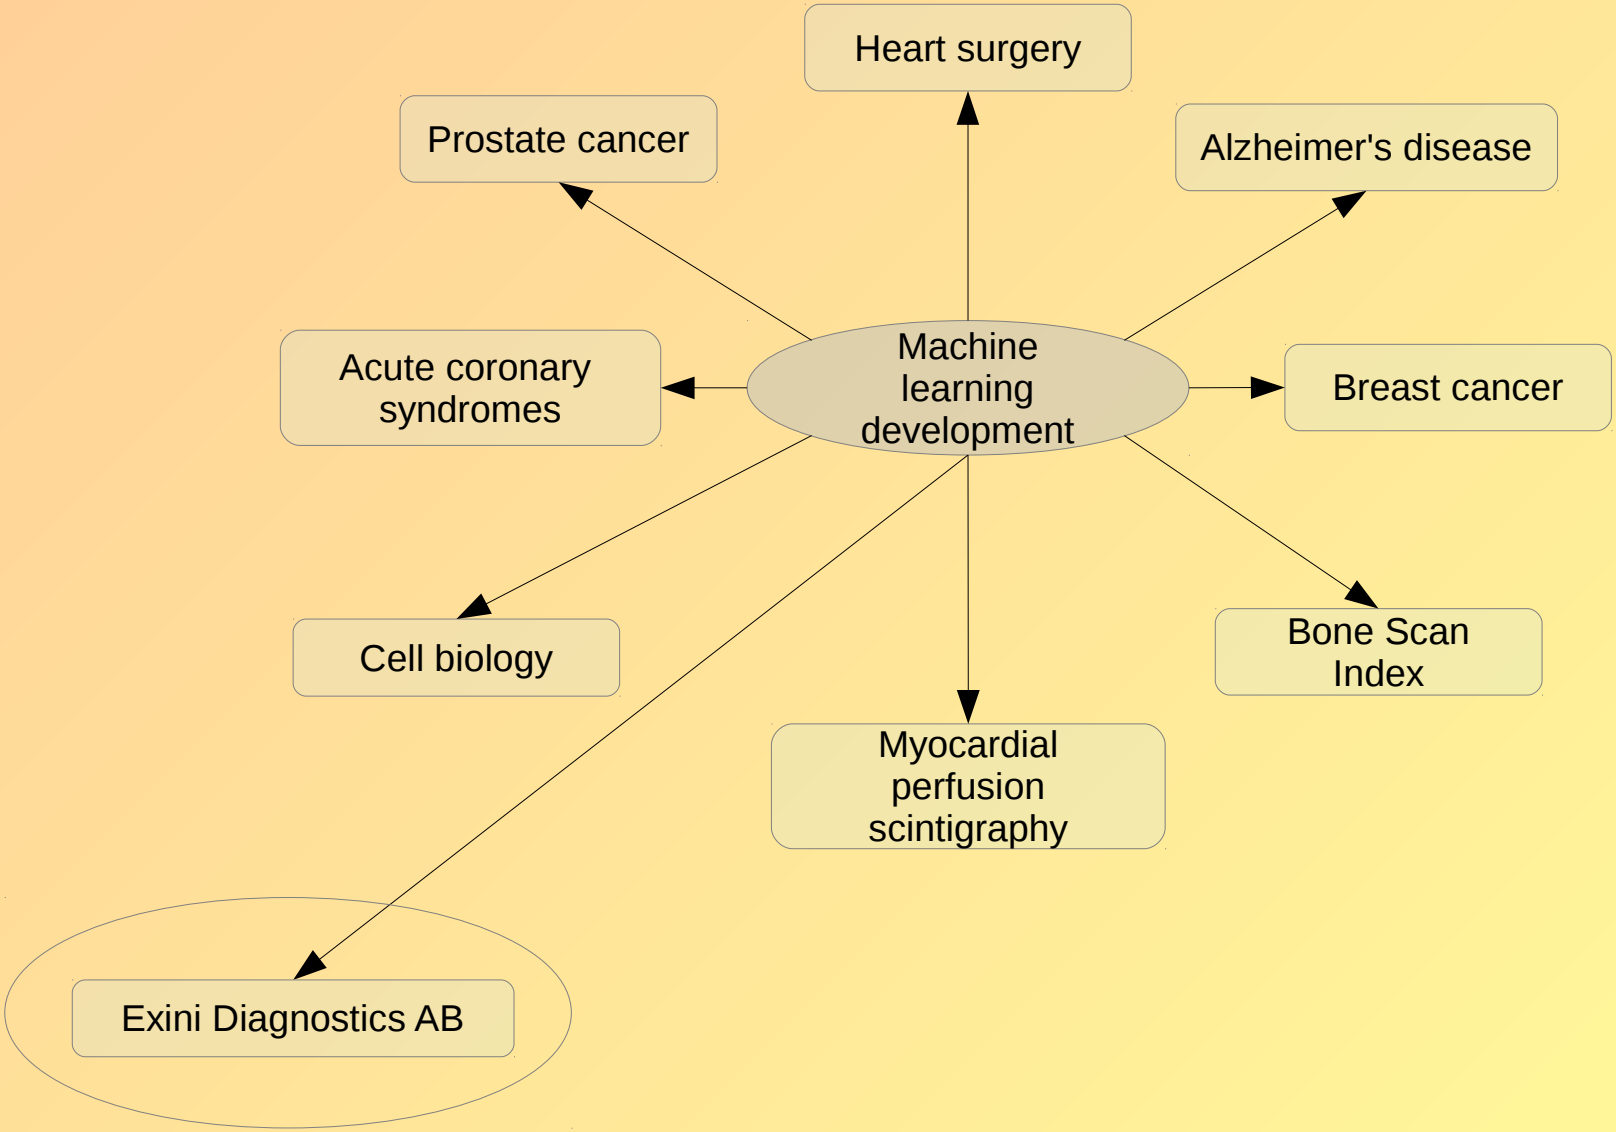
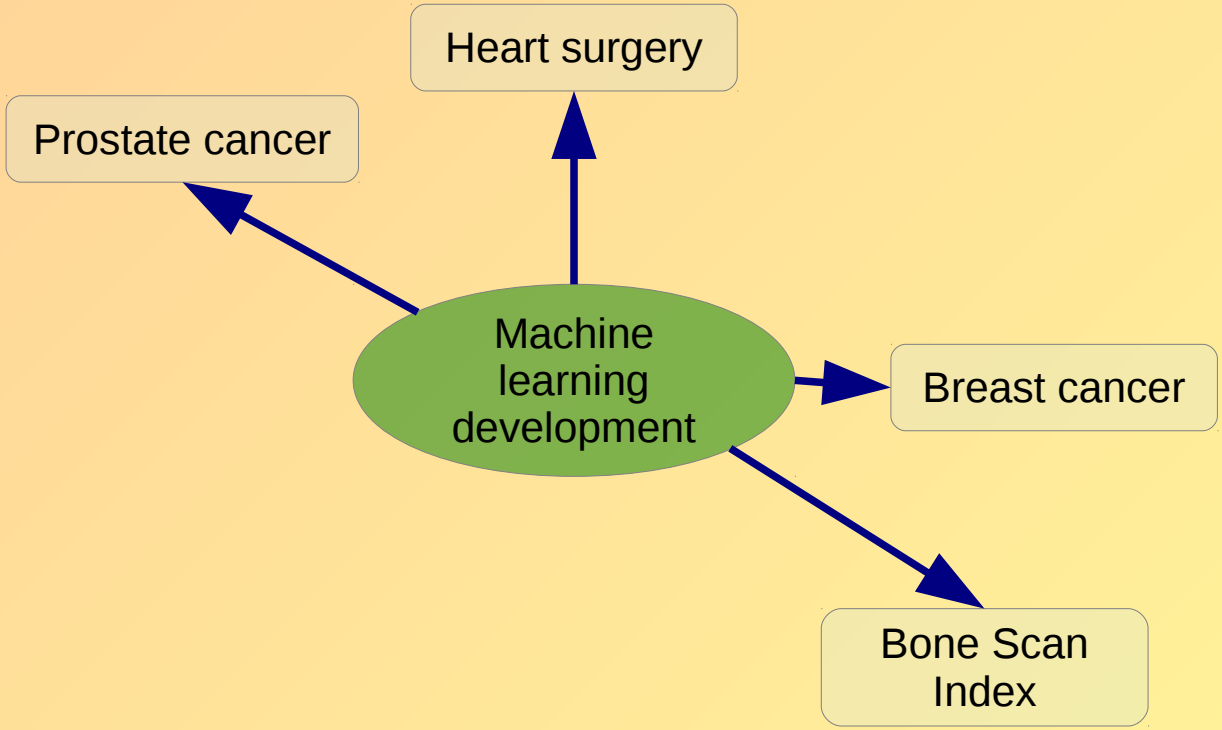
Modeling of survival data and some nice applications in clinical medicine

Mattias Ohlsson

Overview of activities

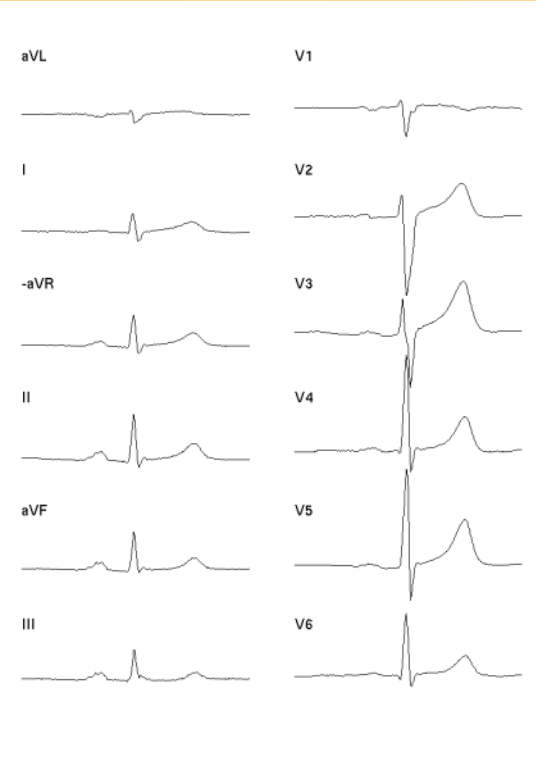


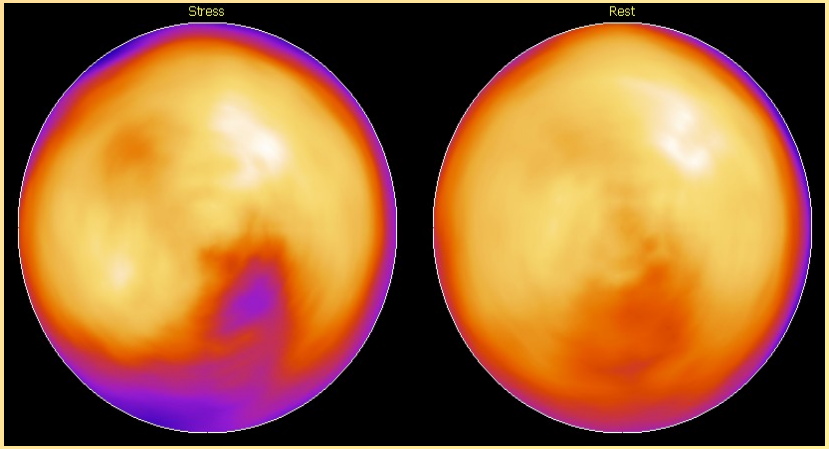
Common theme: survival analysis



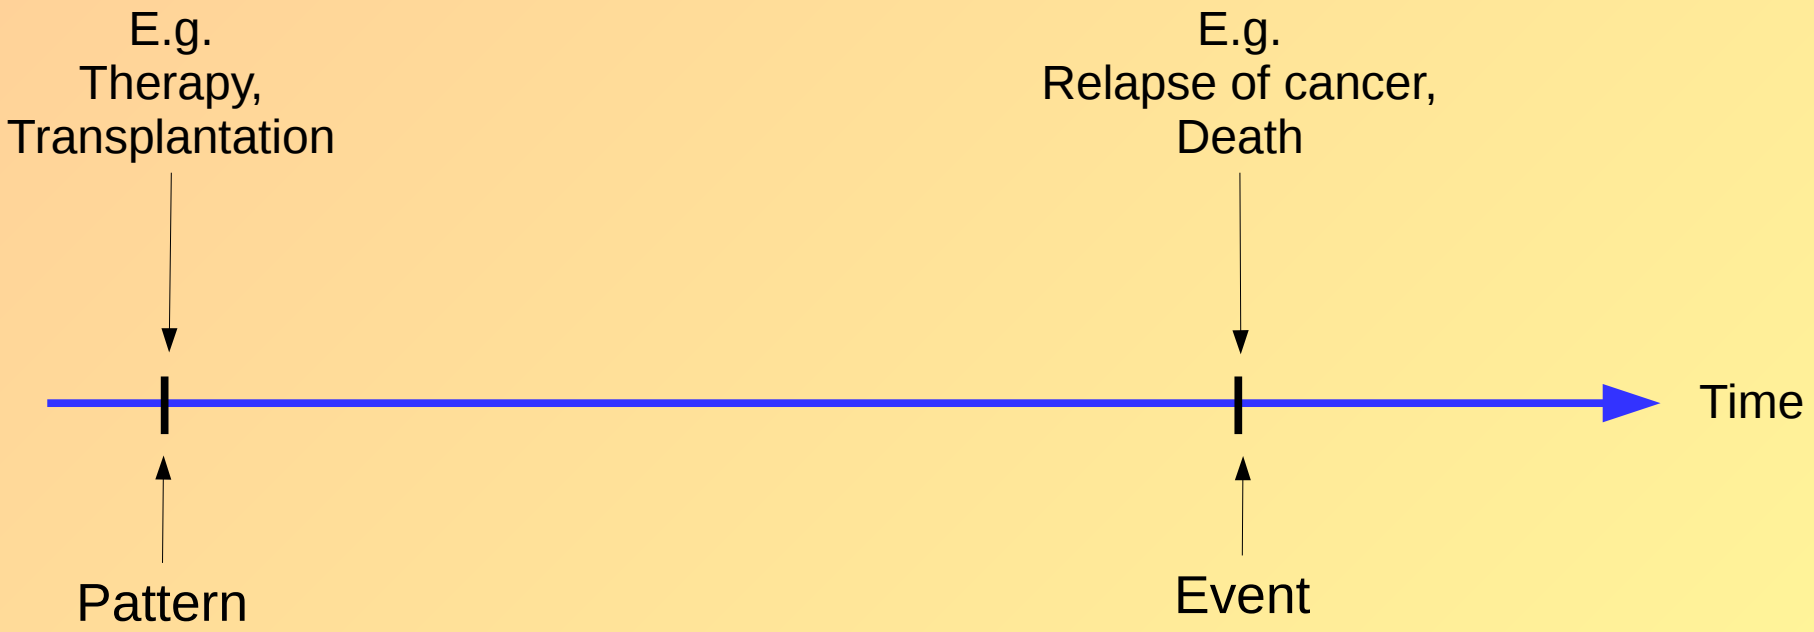
Survival analysis ~ adding a temporal information to pattern recognition problems

“Classical” pattern recognition





Survival analysis ~ analysis of time duration until an event occurs

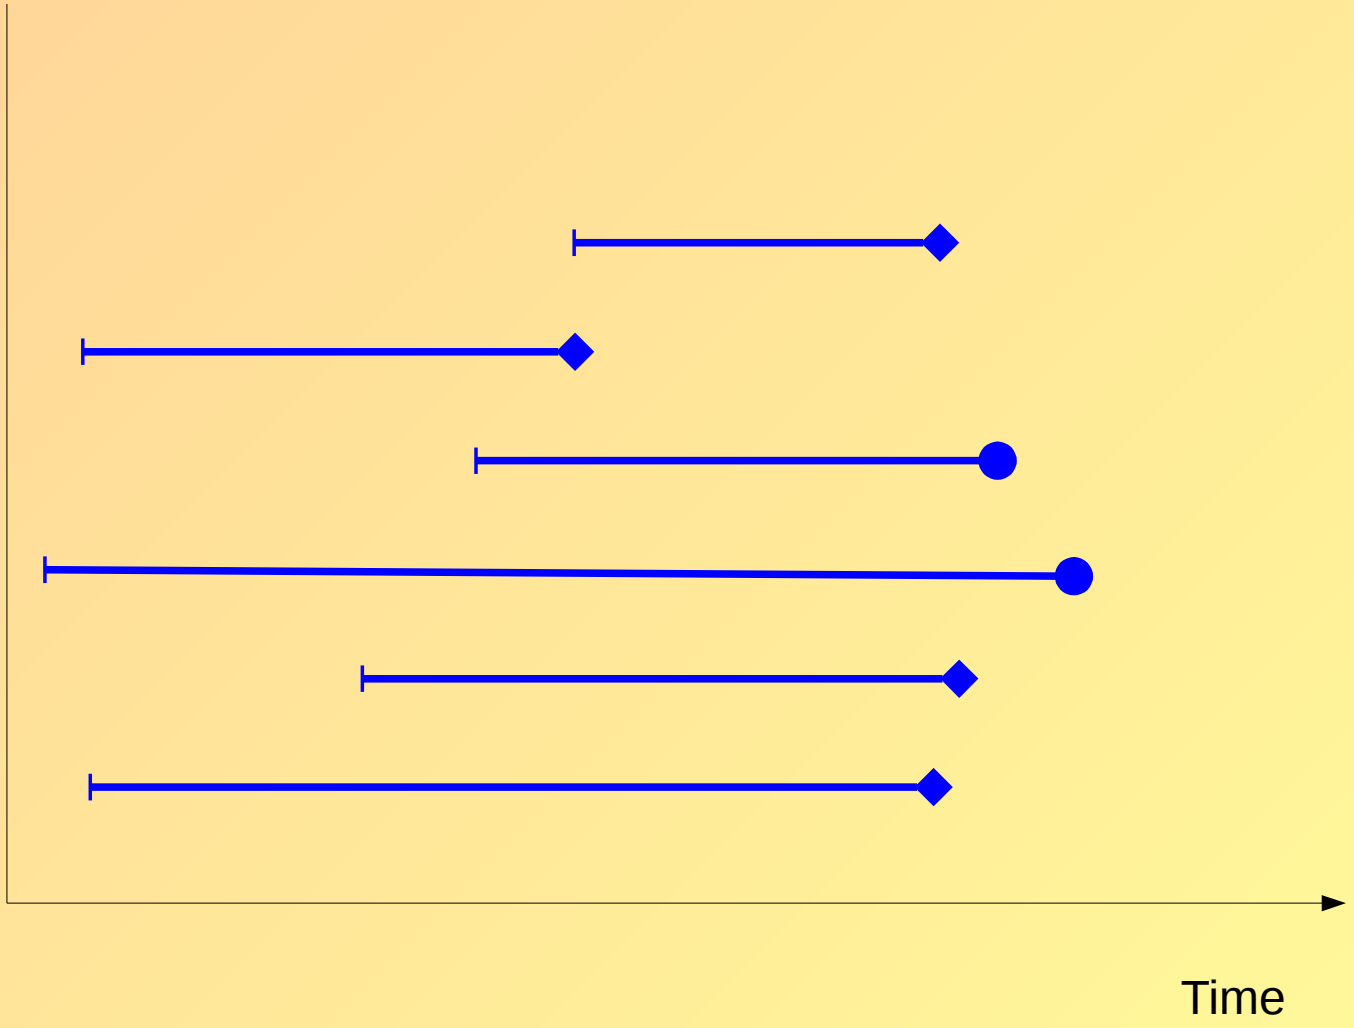


Survival analysis – the data

Pattern information

Event

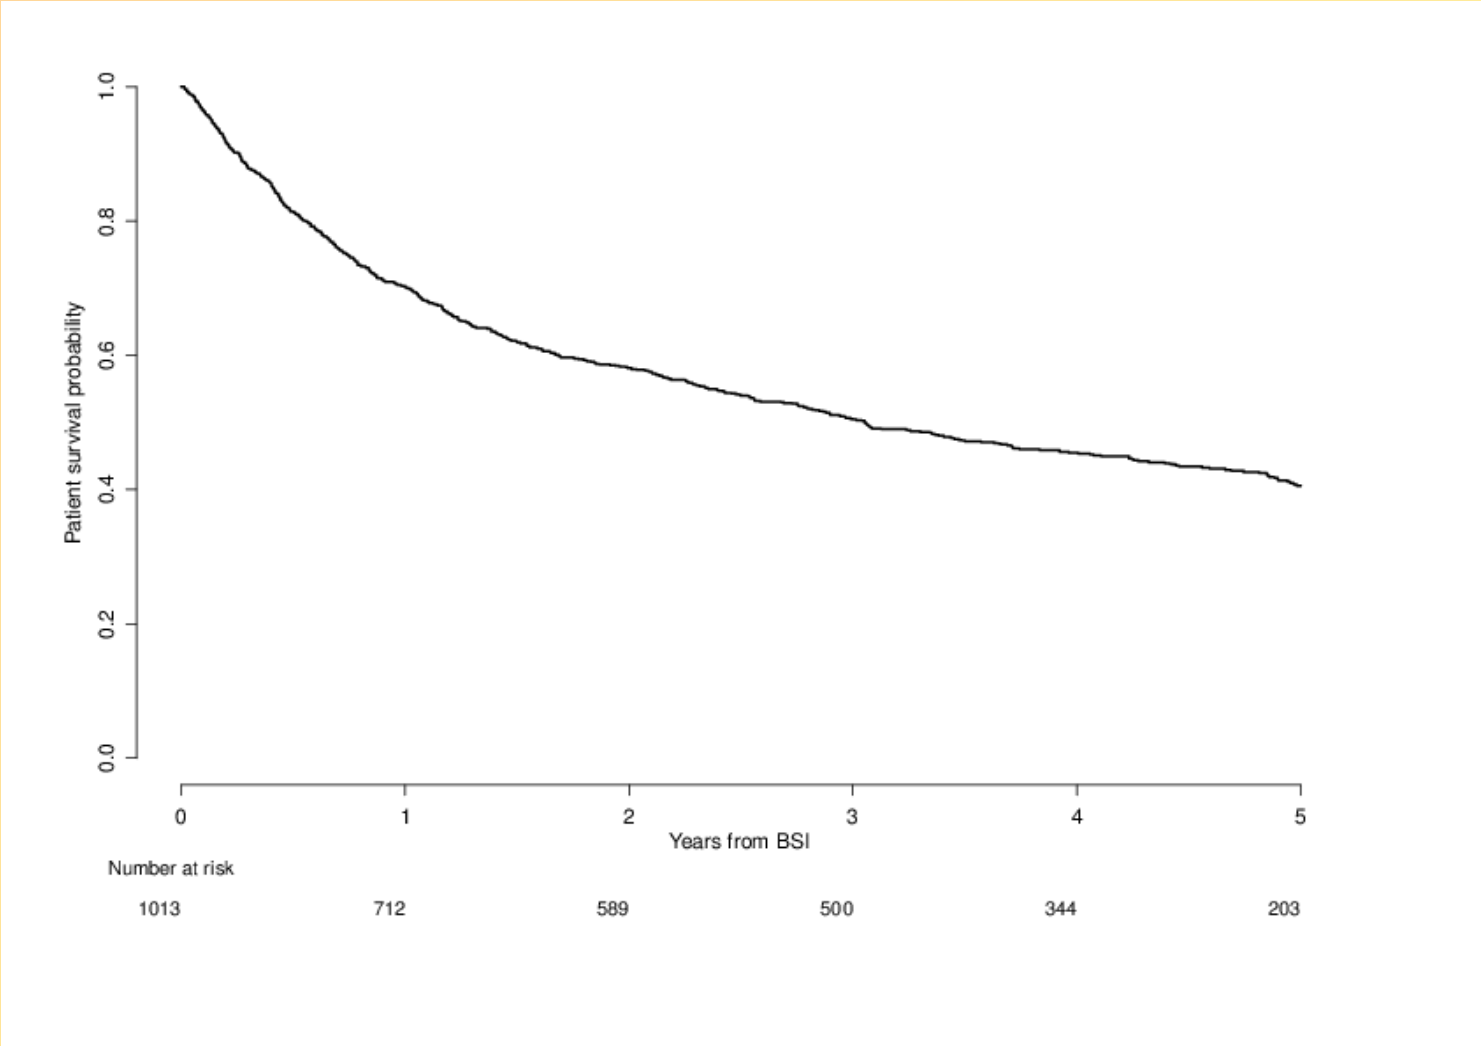
Censored event, eg. still alive, left the study, death because of other reasons etc

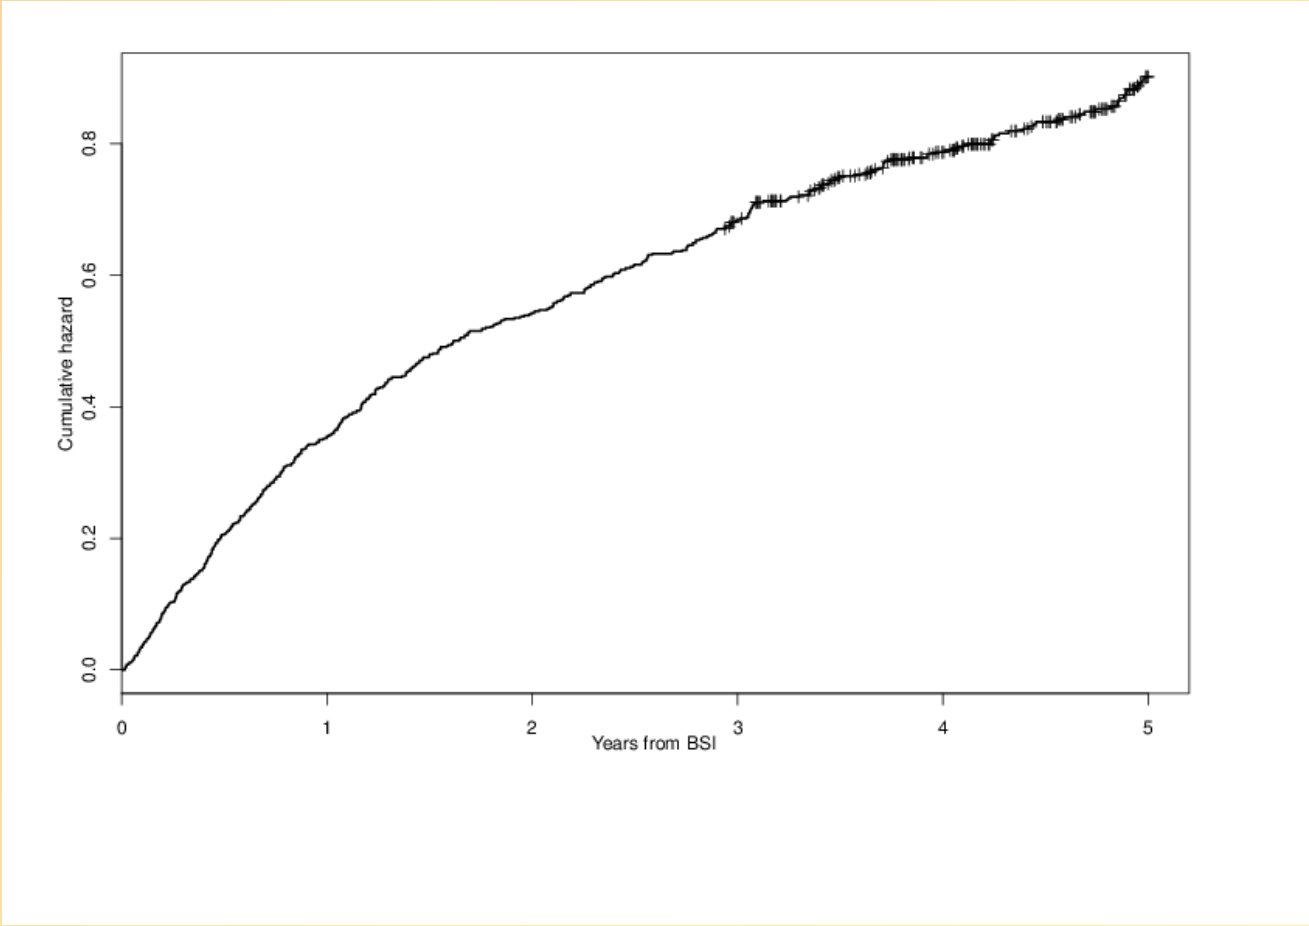


Survival analysis – what do we want to model?

The survival function

$$S(t) = P(T > t)$$





The hazard function

$$h(t) = \lim_{\Delta t \to 0} \frac{P(T < t + \Delta t | T \geq t)}{\Delta t} = -\frac{S'(t)}{S(t)}$$

(event rate at time t conditional on survival until time t or later.
Interpretation: risk of dying at time t)

Imaging biomarker for prostate cancer

Evaluation of the Bone Scan Index

In collaboration with Lars Edenbrandt, Clinical Physiology, Malmö

This project deals with later stages of prostate cancer, specifically when bone metastases occur.

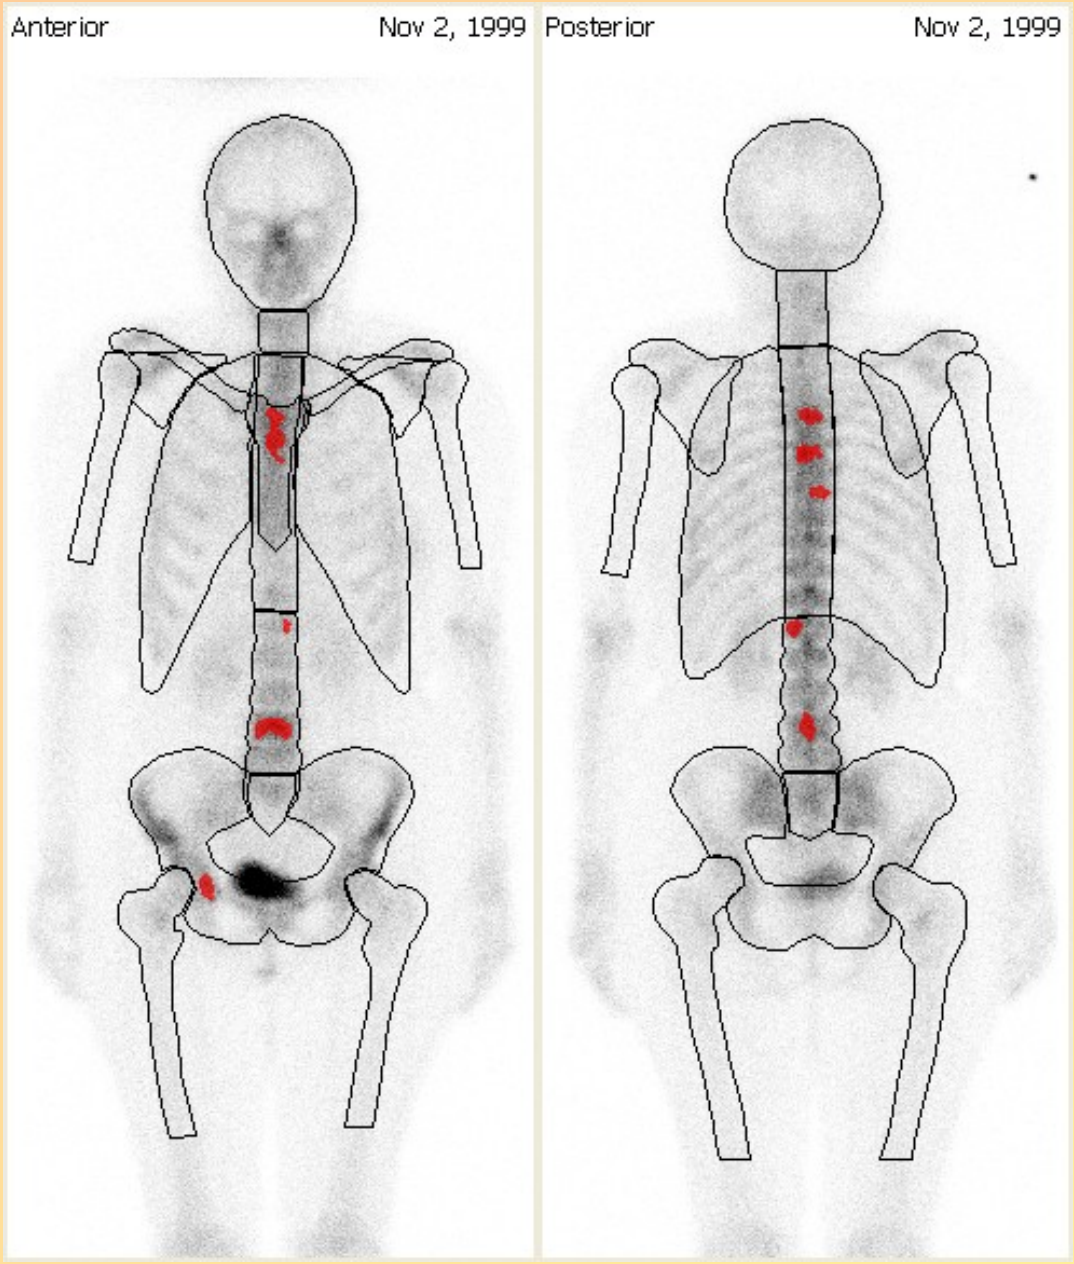
Aim: Characterize the BSI imaging biomarker

- prognosis
- treatment response

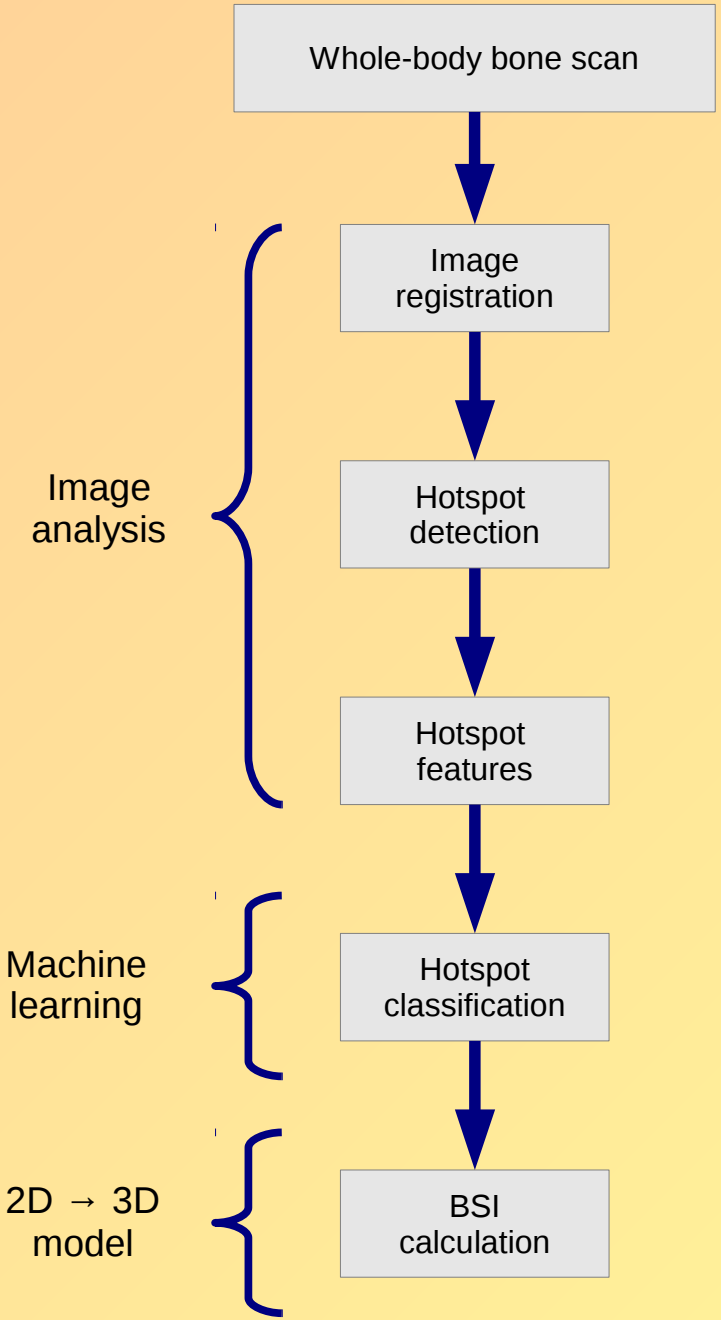
Other common biomarkers or “scores” may not be optimal (e.g. PSA, Gleason score)

BSI = Bone Scan Index

BSI is a method of expressing the tumor burden in the bone as a percentage of the total skeletal mass.



How to calculate BSI?

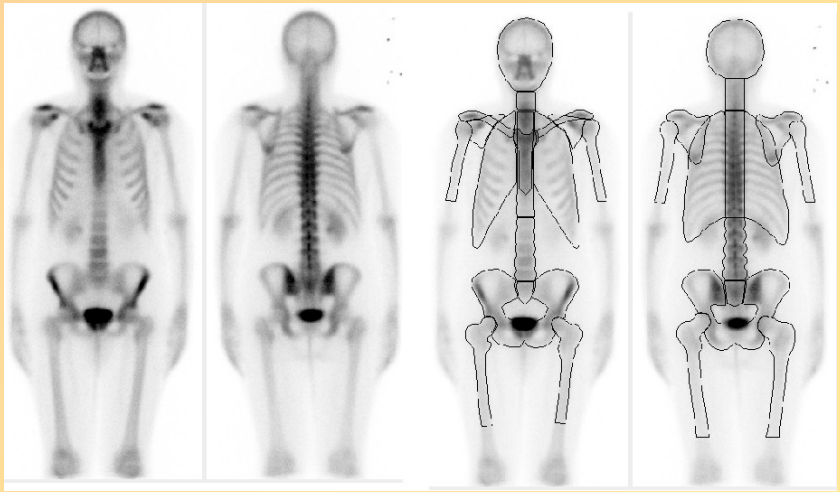


Whole-body bone scan
Image registration
Hotspot detection
Hotspot features
Hotspot classification
BSI calculation
Image analysis
Machine learning
2D → 3D model

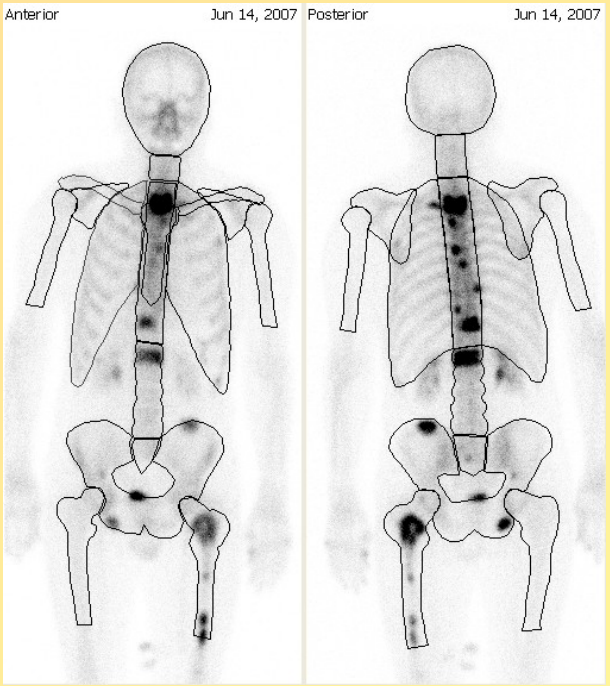
Image registration

Atlas

- Based on ~10 images
- Manual delineation
- 12 anatomical regions



The atlas is registred to the new image using the Morphon method



Hotspot detection

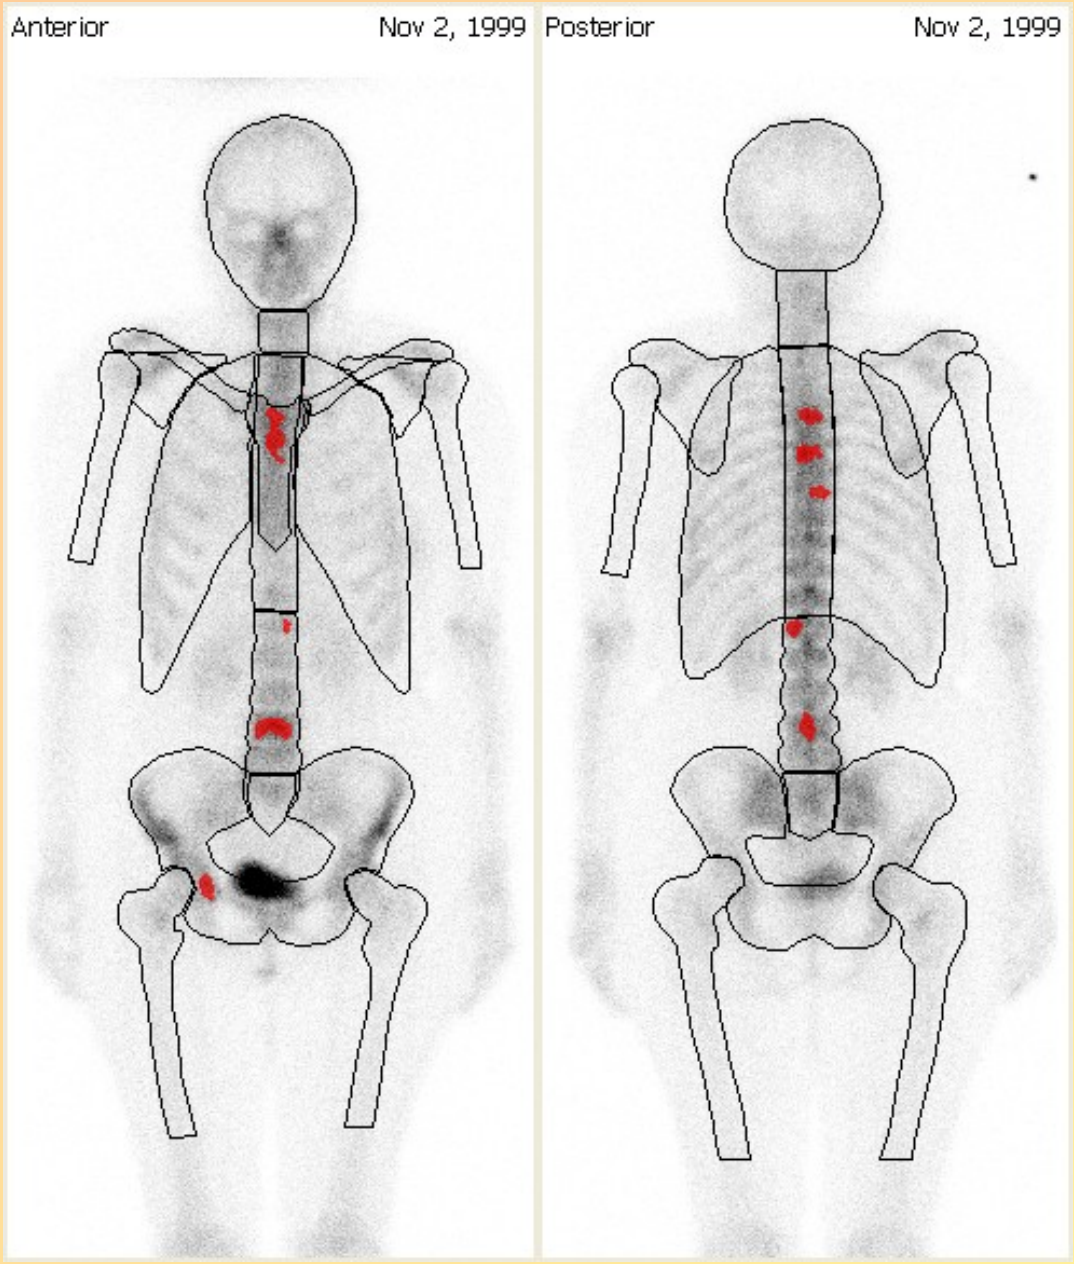
- Find average intensity in ***healthy*** bone tissue
- Normalize using the above average intensity

- Bandpass filtering
- Thresholding

Hotspot features

- Geometry features
- Localization features
- Intensity distribution features
- Other global features capturing the density of hotspots. Both regional and global.

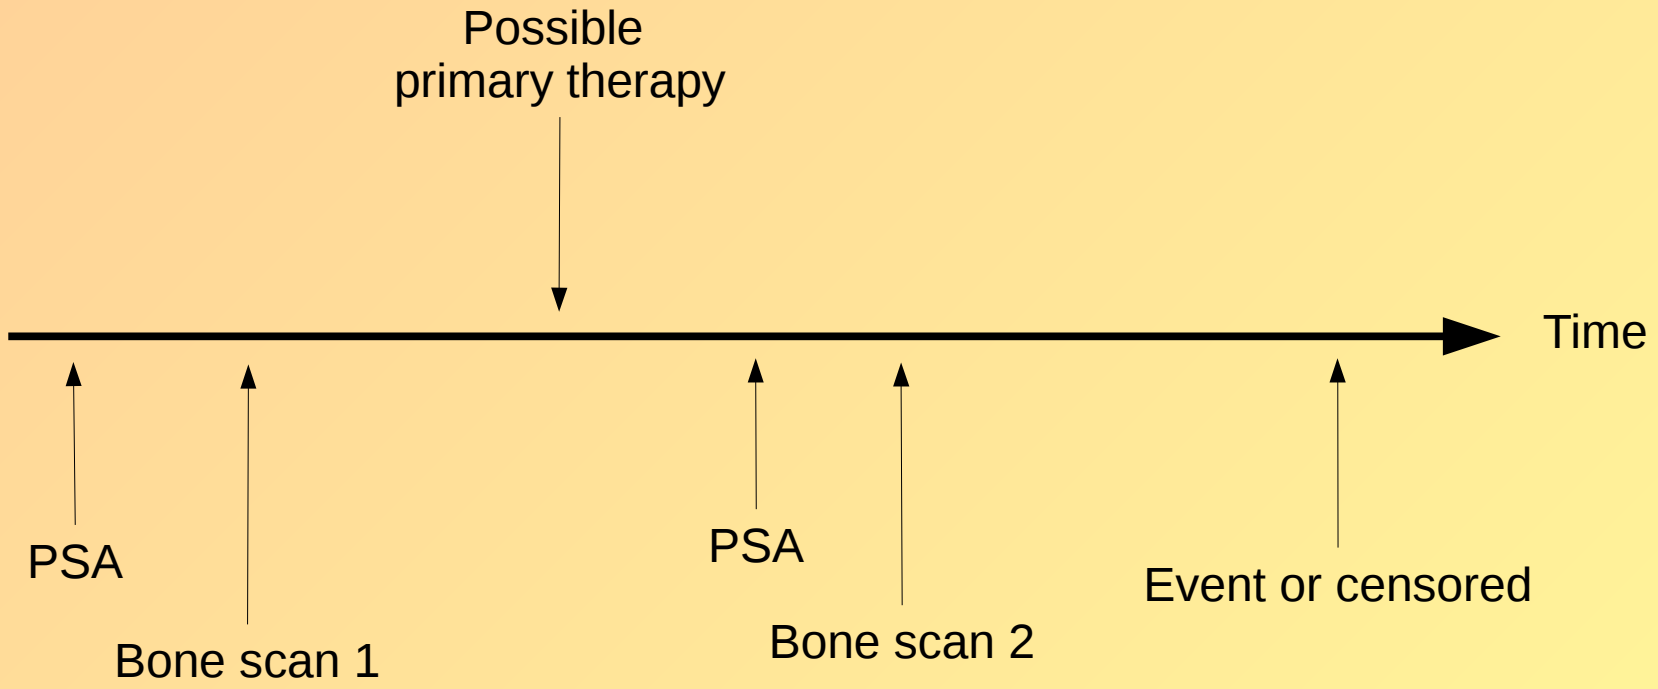
Machine learning



Now we can!

Exini Diagnostics

Data overview



How to model survival?

COX proportional hazard model of survival data –
very common method.

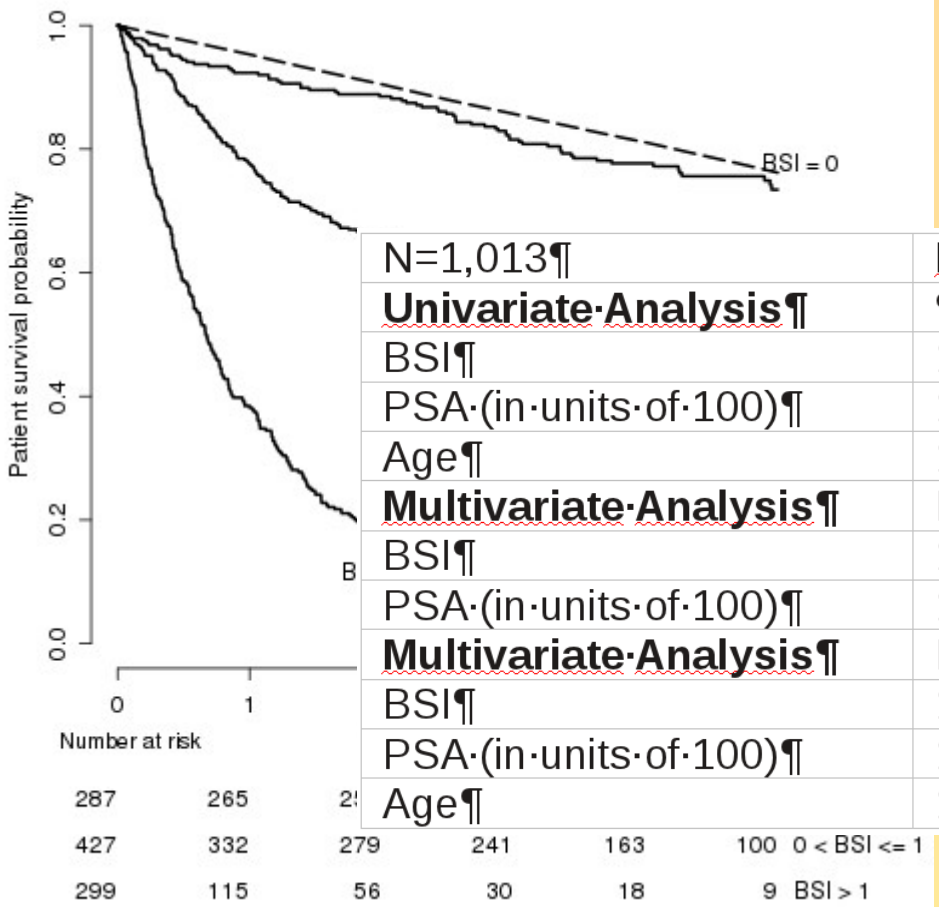
$$h(t, \mathbf{x}) = h_o(t) e^{\beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_n x_n}$$

$\beta_1 \cdots \beta_n$ can be estimated using “maximum partial likelihood”

Relative risk (hazard ratio) becomes simple. For example comparing a unit change of one covariate:

$$\frac{h(t, x)|_{x_i+1}}{h(t, x)|_{x_i}} \equiv HR_{x_i} = e^{\beta_i}$$

Some results



N=1,013¶	**Hazard·Ratio¶**	**p-value¶**	**c-index¶**

Optimal match?

Donor
Demographic data
Age (year)
Female gender
Weight (kg)
Duration of ischemia (min)
CODD: Head trauma
CODD: Cerebrovascular event
Blood group (A,B,AB,O)

One

In total about 140 available “features”

Today

Possible recipients

1. Compatible blood group match
2. Recipient donor weight match ± 20%

Prioritize according to

1. Identical blood group
2. If young donor, select young recipient (< 35 years) or donor age - recipient age < 15 years
3. If PVR > 3.0 then 0-15% larger weight for the donor

Two or more recipients have the same priority then random selection

Aim: Better selection → improved survival

For discrete data $0 < t_1 < t_2 < \cdots < t_L \quad , a_l = (t_{l-1}, t_l]$

Survival function $S(t_l) = P(T > t_l)$

Discrete hazard rate $h_l = -\dfrac{S(t_l) - S(t_{l-1})}{S(t_{l-1})}$

$$S(t) = \prod_{l:t_l \leq t} (1 - h_l)$$

As usual “maximize the likelihood function”

PLANN = Partial logistic regression with ANN

$$h_l(\vec{x}, a_l) \rightarrow y(\vec{x}, a_l)$$

Model these by neural networks

The output from the neural network will provide smoothed estimates of the discrete hazard rates.

A more flexible modeling!

Also add: regularization, ensemble approaches, multiple random imputations etc.

Study Population – ISHLT database

- 56 625 patients that have undergone a heart transplantation
- Mean age was 51 and 21% women.
- Mean follow-up duration of 5.2 years
- Overall 30-day mortality was 9% (n=5010)
- One-year mortality was 18% (n=9380)
- A total of 21 502 patients (38%) died during follow-up.
- Main cause of death was

    - late graft failure (3215)
    - major adverse cardiovascular events (2993)
    - infections (2656)

Also: Scandiatransplant, ~1300 patients, external validation

Submit Defaults

Can we learn something new?

- The model gives you a predicted survival curve for a donor-recipient pair.
- We can measure the “performance” for any given pair (both real and virtual).
- The area under *S(t)* is our measure of performance.

Virtual recipient-donor matching

C-index modeling

In-house development (Patrik E & Jonas K)

C-index (*concordance index*) is a performance measure for survival modeling (with censored data)

$$C = \frac{1}{|\Omega|} \sum_{(i,j)\in\Omega} \mathbf{1}_{\mathbf{f(x_i)<f(x_j)}}$$

$f(x_i) =$ predicted survival time for patient *i*.

$\Omega =$ All pairs of patients (i,j) such that:

- Both *i* and *j* have events and $t_i < t_j$
- Patient *i* have and event and t_i is smaller that patient *j*'s censor time

You do not have to predict the survival time. A prognostic index that can order the patients correctly is sufficient.

$$C = \frac{1}{|\Omega|} \sum_{(i,j)\in\Omega} \mathbf{1}_{\mathbf{f(x_i)<f(x_j)}}$$

The c-index is rank based measure = problems when optimizing the prediction model.

Our approach:

- Use neural networks to compute a prognostic index.

$$p(\mathbf{x}) = \sum_{j=1}^{J} \omega_j \cdot \varphi \left(\sum_{k=1}^{K} \tilde{\omega}_{jk} x_k + \tilde{\omega}_{j0} \right) + \omega_0$$

- Maximize the C-index with respect to model parameters

$$C = \frac{1}{|\Omega|} \sum_{(i,j)\in\Omega} \mathbf{1}_{\mathbf{p(x_i)>p(x_j)}}$$

- We use *genetic algorithms* for the optimization.

- Use en ensemble of networks rather than just a single one.

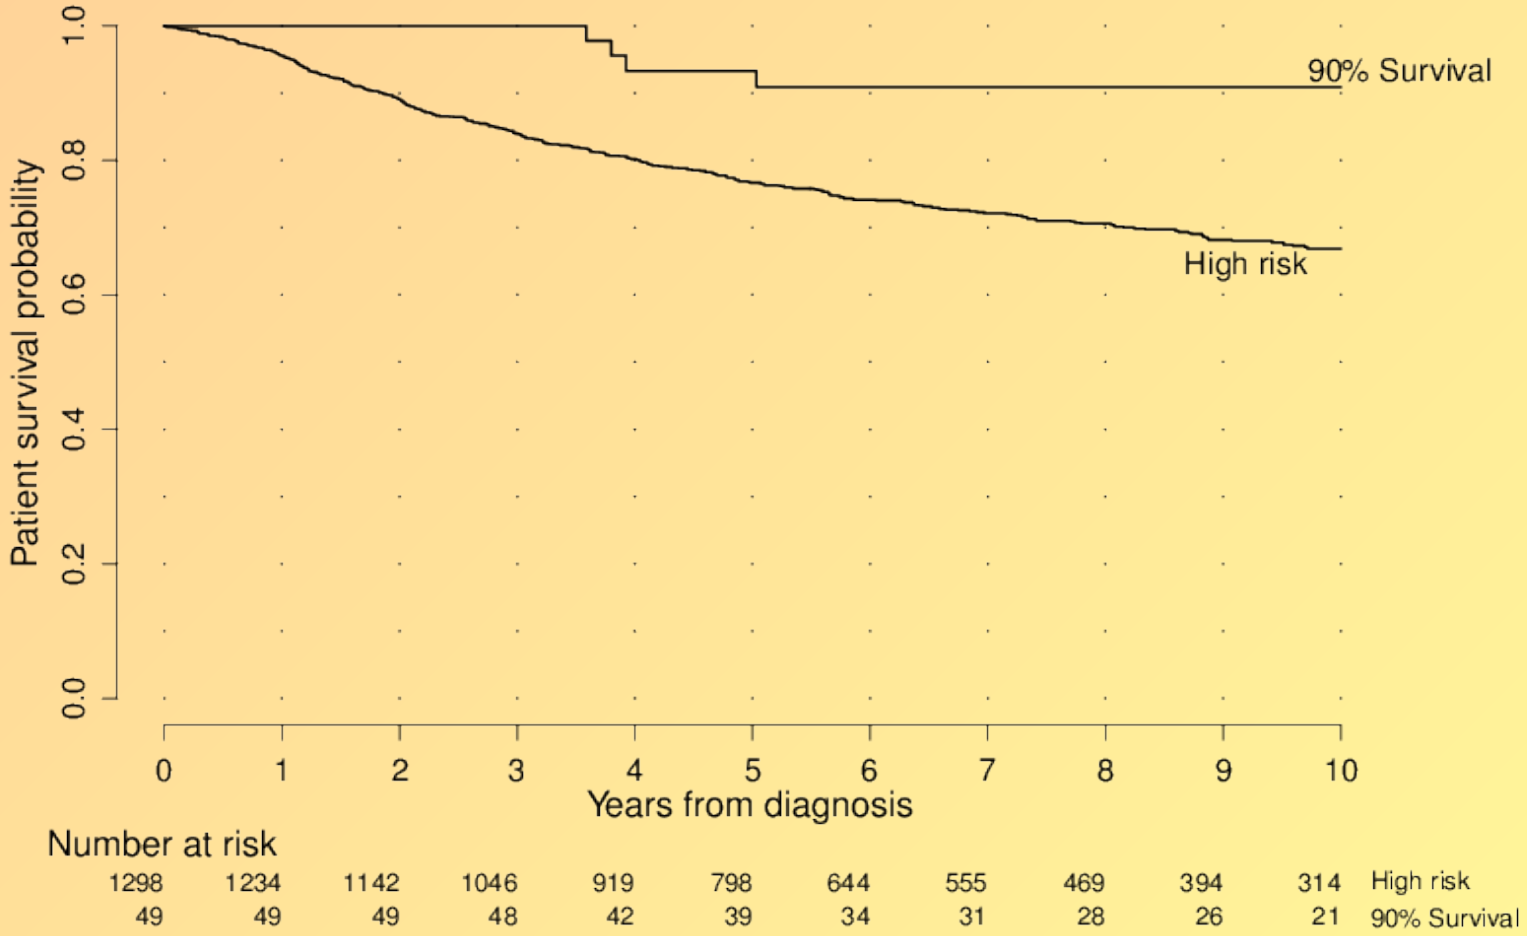
Clinical application

- ~ 4000 female patients with breast cancer, that have had removal of primary tumor.
- Recurrence for about 21% (after 5 years)
- Median age ~ 60 years.

Example of covariates: Age, tumor size, number of positve lymph nodes, HER2-status, histological grade.

Aim: Construct a prognostic index for recurrence

Split into high risk and low risk group based on the index



Extension: Predict actual survival times.

$$E = \frac{1}{N} \sum_n q_n (\hat{t}(\mathbf{x}_n) - t_n)^2$$

Machine learning model

Correct for censored cases $q_n \equiv \delta_n + (1 - \delta_n) \cdot I(t_n > \hat{t}_n)$

More extension: Use more information from the censored cases
